(Received 18 March 2007; revised manuscript received 22 August 2007; published 10 October 2007)

We investigate a simple dynamical model of a microtubule that evolves by attachment of guanosine triphosphate (GTP) tubulin to its end, irreversible conversion of GTP to guanosine diphosphate (GDP) tubulin by hydrolysis, and detachment of GDP at the end of a microtubule. As a function of rates of these processes, the microtubule can grow steadily or its length can fluctuate wildly. In the regime where detachment can be neglected, we find exact expressions for the tubule and GTP cap length distributions, as well as power-law length distributions of GTP and GDP islands. In the opposite limit of instantaneous detachment, we find the time between catastrophes, where the microtubule shrinks to zero length, and determine the size distribution of avalanches (sequence of consecutive GDP detachment events). We obtain the phase diagram for general rates and verify our predictions by numerical simulations.

I. INTRODUCTION AND MODEL

Microtubules are polar linear polymers that perform major organizational tasks in living cells [1,2]. Through a unique feature of microtubule assembly, termed dynamic instability [3], they function as molecular machines [4] that move cellular structures during processes such as cell reproduction [2,5]. A surprising feature of microtubules is that they remain out of equilibrium under fixed external conditions and can undergo alternating periods of rapid growth and even more rapid shrinking (Fig. 1).

These sudden polymerization changes are driven by the interplay between several fundamental processes. Microtubules grow by the attachment of guanosine triphosphate tubulin complexes (GTP) at one end [3,6]. Structural studies indicate that the end of a microtubule must consist of a “cap” of consecutive GTP monomers [7] for growth to continue [6]. Once polymerized, the GTP of this complex can irreversibly hydrolyze into guanosine diphosphate (GDP). If all the monomers in the cap convert to GDP, the microtubule is destabilized and rapid shrinkage ensues by the detachment of GDP tubulin units. The competition between GTP attachment and hydrolysis from GTP to GDP is believed to lead to the dynamic instability in which the GTP cap hydrolyzes to GDP and then the microtubule rapidly depolymerizes. The stochastic attachment of GTP can, however, lead to a rescue to the growing phase before the microtubule length shrinks to zero [1,8].

The origin of this dynamic instability has been actively investigated. One avenue of theoretical work on this dynamical instability is based on models of mechanical stability [9–11]. For example, a detailed stochastic model of a microtubule that includes all of the 13 constituent protofilaments has been investigated in [10]. By using model parameters that were inferred from equilibrium statistical physics, VanBuren *et al.* [10] found some characteristics of microtubule evolution that agreed with experimental data [12]. The disadvantage of this detailed modeling, however, is its complexity, so that it is generally not possible to develop an intuitive understanding of microtubule evolution.

Another approach for modeling the dynamics of microtubules is based on effective two-state models that describe the dynamics in terms of a switching between a growing and a shrinking state [8,13–17]. The essence of many of these models is that a microtubule exists either in a growing phase (where a GTP cap exists at the end of the microtubule) or a shrinking phase (without a GTP cap), and that there are stochastic transitions between these two states. By tuning parameters appropriately, it is possible to reproduce the phase changes between the growing and shrinking phases of microtubules that have been observed experimentally [3]. While the two-state model has the advantage of having only few parameters, a constant rate of switching between a growing and shrinking microtubule is built into the model. Thus, switching models cannot account for the stochastic avalanches and catastrophes that occur in real microtubules.

On the other hand, a minimalist model of microtubule dynamics has been proposed and investigated by Flyvbjerg *et al.* [18]. In their model, they dispense with attempts to capture all of the myriad of experimental parameters within a detailed model, but instead constructed an effective continuous theory to describe microtubule dynamics. Their goal was to construct an effective theory that contained as few details as possible. As stated in Ref. [18], they envision that their effective theory should be derivable from a fundamental, microscopic theory and its parameters.

This minimalist modeling is the approach that we adopt in the present work. We investigate a recently introduced [19,20] kinetic model that accounts for many aspects of microtubule evolution. Our main result is that only a few essential parameters with simple physical interpretations are needed to describe the rich features of microtubule growth, catastrophes, and rescues [21].

We treat a microtubule as a linear polymer that consists of GTP or GDP monomers that we denote as + and –, respectively. To emphasize this connection between chemistry and the model, we will write the former as GTP^+ and the latter as GDP^- . The state of a microtubule evolves due to the following three processes:

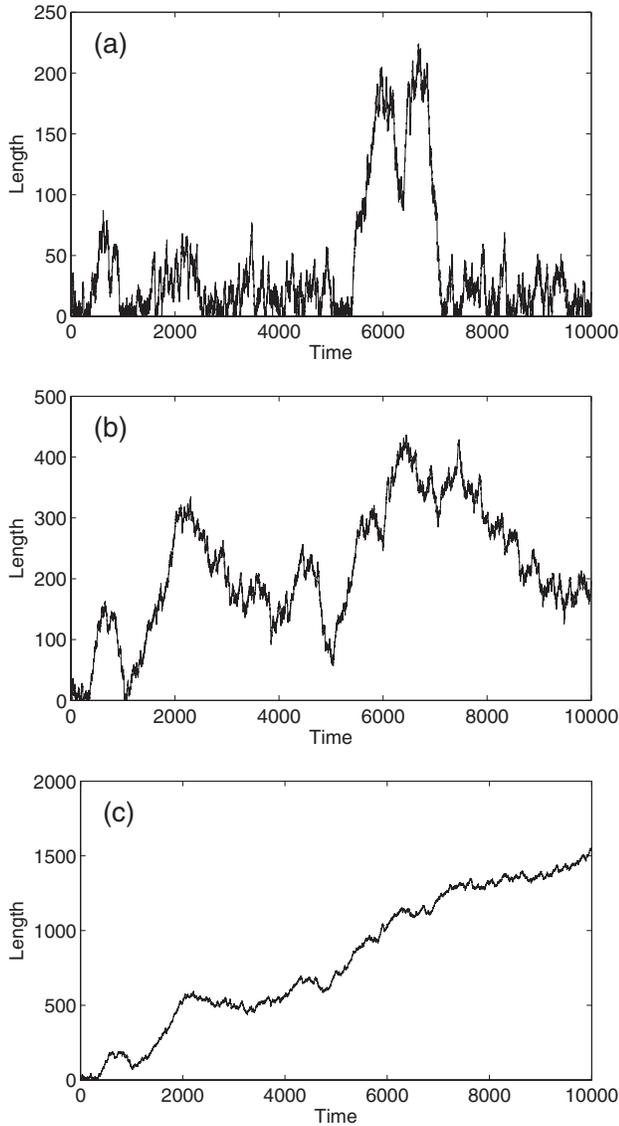

FIG. 1. Numerical simulations of typical microtubule lengths versus time for detachment rate $\mu=5$ and attachment rates: (a) $\lambda=1.4$, where the microtubule generally remains short, (b) $\lambda=1.5$, where the length fluctuates strongly, and (c) $\lambda=1.6$, where the microtubule grows nearly steadily.

(1) *Attachment.* A microtubule grows by attachment of a guanosine triphosphate (GTP⁺) monomer,

(2) *Conversion.* Once part of the microtubule, each GTP⁺ can independently convert by hydrolysis to a guanosine diphosphate (GDP⁻),

(3) *Detachment.* A microtubule shrinks due to detachment of a GDP⁻ monomer only from the end of the microtubule,

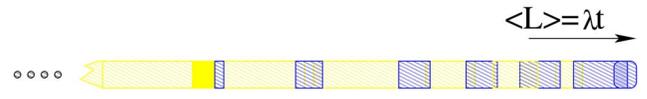

FIG. 2. (Color online) Cartoon of a microtubule in unrestricted growth. Regions of GTP⁺ are shown dark (blue) shading and regions of GDP⁻ are light (yellow) shading. The GTP⁺ regions get shorter further from the tip that advances as λt , while the GDP⁻ regions get longer.

Here the symbols $|$ and \rangle denote the terminal and the active end of the microtubule. It is worth mentioning that these steps are similar to those in a recently introduced model of DNA sequence evolution [22], and that some of the results about the structure of DNA sequences seem to be related to our results about island size distributions in microtubules.

Generically, the (λ, μ, p) phase space separates into a region where the microtubule grows (on average) with a certain rate $V(\lambda, \mu, p)$, and a compact phase where the average microtubule length is finite. These two phases are separated by a phase boundary $\mu = \mu_*(\lambda, p)$ along which the growth rate $V(\lambda, \mu, p)$ vanishes. While the behavior of a microtubule for general parameter values is of interest, we will primarily focus on extreme values of the governing parameters where we can obtain a detailed statistical characterization of the microtubule structure. For certain properties, such as the shape of the phase diagram, we will also present results of numerical simulations of the model.

In Sec. II, we study the evolution of a microtubule under unrestricted growth conditions—namely no detachment and an attachment rate that does not depend on the identity of the last monomer. Our results here are relevant to understanding the distribution of cap length and the diffusion coefficient of the tip of the microtubule in the growth phase. The predictions of the model in this limit could also be useful in understanding the binding pattern of proteins to microtubules [23]. Since proteins are important regulatory factors in microtubule polymerization, these results could prove useful in interpreting the effects of proteins on microtubule growth.

By a master equation approach, we will determine both the number of GTP⁺ monomers on a microtubule, as well as the length distributions of GTP⁺ and GDP⁻ islands (Fig. 2). Many of these analytical predictions are verified by numerical simulations. In Sec. III, we extend our approach to the case of constrained growth, $p \neq 1$, in which microtubule growth depends on whether the last monomer is a GTP⁺ or a GDP⁻. In Sec. IV, we investigate the phenomenon of “catastrophe” for infinite detachment rate μ , in which a microtubule shrinks to zero length when all of its constituent monomers convert to GDP⁻. We derive the asymptotic behavior of the catastrophe probability by expressing it as an infinite product and recognizing the connection of this product with modular functions. We also determine the asymptotic behavior of the size distribution of avalanches, namely, sequences of consecutive GDP⁻ detachment events. Finally, in Sec. V, we discuss the behavior of a microtubule for general parameter values through a combination of numerical and analytic results. Here numerical simulations are useful to extract

quantitative results for parameter values that are not amenable to theoretical analysis. Several calculational details are given in the appendices.

II. UNRESTRICTED GROWTH

We define unrestricted growth as the limit of detachment rate $\mu=0$, so that a microtubule grows without bound. Here we consider the special case where the attachment rate does not depend on the identity of the last monomer; that is, the limit of $p=1$, where the attachment is unconstrained. Because of the latter condition, the number N of GTP⁺ monomers decouples from the number of GDP⁻, a greatly simplifying feature.

A. Distribution of positive monomers

The average number of GTP⁺ monomers evolves as

$$\frac{d}{dt}\langle N \rangle = \lambda - \langle N \rangle. \quad (1)$$

The gain term accounts for the adsorption of a GTP⁺ at rate λ , while the loss term accounts for the conversion events GTP⁺ \rightarrow GDP⁻, each of which occurs with rate 1. Thus $\langle N \rangle$ approaches its stationary value of λ exponentially quickly,

$$\langle N \rangle = \lambda(1 - e^{-t}). \quad (2)$$

More generally, consider the probability $\Pi_N(t)$ that there are N GTP⁺ monomers at time t . This probability evolves according to

$$\frac{d\Pi_N}{dt} = -(N + \lambda)\Pi_N + \lambda\Pi_{N-1} + (N + 1)\Pi_{N+1}. \quad (3)$$

The loss term $(N + \lambda)\Pi_N$ accounts for conversion events GTP⁺ \rightarrow GDP⁻ that occur with total rate N , and the attachment of a GTP⁺ at the end of the microtubule of length N with rate λ . The gain terms can be explained similarly.

In terms of generating function $\Pi(z) \equiv \sum_{N=0}^{\infty} \Pi_N z^N$, Eq. (3) can be recast as the differential equation

$$\frac{\partial \Pi}{\partial t} = (1 - z) \left(\frac{\partial \Pi}{\partial z} - \lambda \Pi \right). \quad (4)$$

Introducing $Q = \Pi e^{-\lambda z}$ and $y = \ln(1 - z)$, we transform Eq. (4) into the wave equation

$$\frac{\partial Q}{\partial t} + \frac{\partial Q}{\partial y} = 0, \quad (5)$$

whose solution is an arbitrary function of $t - y$ or, equivalently, $(1 - z)e^{-t}$. If the system initially is a microtubule of zero length, $\Pi_N(t=0) = \delta_{N,0}$, the initial generating function $\Pi(z, t=0) = 1$, so that $Q = e^{-\lambda z} = e^{\lambda(1-z)} e^{-\lambda}$. Thus, for $t > 0$, $Q = e^{\lambda(1-z)e^{-t}} e^{-\lambda}$, from which

$$\Pi(z, t) = e^{-\lambda(1-z)(1-e^{-t})}. \quad (6)$$

Expanding this expression in a power series in z , the probability for the system to contain N GTP⁺ monomers is the time-dependent Poisson distribution

$$\Pi_N(t) = \frac{[\lambda(1 - e^{-t})]^N}{N!} e^{-\lambda(1 - e^{-t})}. \quad (7)$$

From this result, the mean number of GTP⁺ monomers and its variance are

$$\langle N \rangle = \langle N^2 \rangle - \langle N \rangle^2 = \lambda(1 - e^{-t}). \quad (8)$$

B. Tubule length distributions

The length distribution $P(L, t)$ of the microtubule evolves according to the master equation

$$\frac{dP(L, t)}{dt} = \lambda[P(L - 1, t) - P(L, t)]. \quad (9)$$

For the initial condition $P(L, 0) = \delta_{L,0}$, the solution is again the Poisson distribution

$$P(L, t) = \frac{(\lambda t)^L}{L!} e^{-\lambda t}, \quad (10)$$

from which the average and the variance are

$$\langle L \rangle = \lambda t, \quad \langle L^2 \rangle - \langle L \rangle^2 = \lambda t. \quad (11)$$

Thus the growth rate of the microtubule and the diffusion coefficient of the tip are

$$V = \lambda, \quad D = \lambda/2. \quad (12)$$

A more comprehensive description is provided by the joint distribution $P(L, N, t)$, that a microtubule has length L and contains N GTP⁺ monomers at time t . This distribution evolves as

$$\begin{aligned} \frac{dP(L, N)}{dt} &= \lambda P(L - 1, N - 1) - (N + \lambda)P(L, N) \\ &\quad + (N + 1)P(L, N + 1). \end{aligned} \quad (13)$$

This joint distribution does not factorize, that is, $P(L, N, t) \neq P(L, t)\Pi_N(t)$, because $\langle LN \rangle \neq \langle L \rangle \langle N \rangle$. To demonstrate this inequality, we compute $\langle LN \rangle$ by multiplying Eq. (13) by LN and summing over all $L \geq N \geq 0$ to give

$$\frac{d}{dt} \langle LN \rangle = \lambda(\langle L \rangle + \langle N \rangle + 1) - \langle LN \rangle. \quad (14)$$

Using Eqs. (8) and (11) for $\langle N \rangle$ and $\langle L \rangle$ and integrating we obtain

$$\langle LN \rangle = \lambda^2 t(1 - e^{-t}) + \lambda(1 - e^{-t}) = \langle L \rangle \langle N \rangle + \langle N \rangle. \quad (15)$$

Using Eq. (11), we have $\langle LN \rangle = \langle L \rangle \langle N \rangle (1 + \frac{1}{\lambda t})$, so that the joint distribution is factorizable asymptotically. For completeness, we give the full solution for $P(L, N, t)$ in Appendix A.

C. Cap length distribution

Because of the conversion process GTP⁺ \rightarrow GDP⁻, the tip of the microtubule is comprised predominantly of GTP⁺, while the tail exclusively consists of GDP⁻. The region from

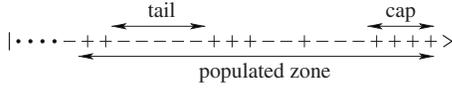

FIG. 3. Representative configuration of a microtubule, with a GTP⁺ cap of length 4, then three GTP⁺ islands of lengths 1, 3, and 2, and three GDP⁻ islands of lengths 3, 2, and a “tail” of length 5. The rest of the microtubule consists of GDP⁻.

the tip until the first monomer is known as the *cap* (Fig. 3) and it plays a fundamental role in microtubule function. We now use the master equation approach to determine the cap length distribution.

Consider a cap of length k . Its length increases by 1 due to the attachment of a GTP⁺ at rate λ . The conversion of any GTP⁺ into a GDP⁻ at rate 1 reduces the cap length from k to an arbitrary value $s < k$. These processes lead to the following master equation for the probability n_k , that the cap length is equal to k :

$$\dot{n}_k = \lambda(n_{k-1} - n_k) - kn_k + \sum_{s \geq k+1} n_s. \quad (16)$$

Equation (16) is also valid for $k=0$ if we set $n_{-1} \equiv 0$. Note that $n_0 \equiv \text{Prob}\{-\}$ is the probability for a cap of length zero. We now solve for the stationary distribution by summing the first $k-1$ of Eq. (16) with \dot{n}_k set to zero to obtain

$$n_{k-1} = \frac{k}{\lambda} \sum_{s \geq k} n_s. \quad (17)$$

The cumulative distribution, $N_k = \sum_{s \geq k} n_s$, thus satisfies the recursion

$$N_k = \frac{\lambda}{k + \lambda} N_{k-1}. \quad (18)$$

Using the normalization $N_0 = 1$ and iterating, we obtain the solution in terms of the gamma function [24]

$$N_k = \frac{\lambda^k \Gamma(1 + \lambda)}{\Gamma(k + 1 + \lambda)}. \quad (19)$$

Hence, the cap length distribution is

$$n_k = \frac{\Gamma(1 + \lambda)}{\Gamma(k + 2 + \lambda)} (k + 1) \lambda^k \quad (20)$$

and the first few terms are

$$n_0 = \frac{1}{1 + \lambda}, \quad n_1 = \frac{2\lambda}{(1 + \lambda)(2 + \lambda)},$$

$$n_2 = \frac{3\lambda^2}{(1 + \lambda)(2 + \lambda)(3 + \lambda)}. \quad (21)$$

Results of direct simulation of the kinetic model are compared to the predicted cap length distribution [Eq. (20)] in Fig. 4. Because of the finite length of the simulated microtubule, there is a largest cap length that is accessible numerically. Aside from this limitation, the simulations results are in agreement with theoretical predictions.

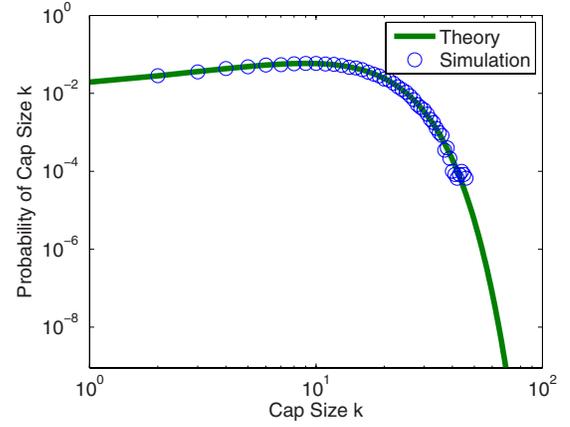

FIG. 4. (Color online) Cap length distribution obtained from simulations at $\mu=0$, $\lambda=100$, and $p=1$ compared to the theoretical prediction of Eq. (20).

It is instructive to determine the dependence of the average cap length $\langle k \rangle = \sum_{k \geq 0} k n_k$ on λ . Using $n_k = N_k - N_{k+1}$, we rearrange $\langle k \rangle$ into

$$\langle k \rangle = \sum_{k \geq 1} N_k. \quad (22)$$

Using (19), the above sum may be written in terms of the confluent hypergeometric series [24]:

$$\langle k \rangle = -1 + F(1; 1 + \lambda; \lambda). \quad (23)$$

We now determine the asymptotic behavior of $\langle k \rangle$ by using the integral representation

$$F(a; b; z) = \frac{\Gamma(b)}{\Gamma(b-a)\Gamma(a)} \int_0^1 dt e^{zt} t^{a-1} (1-t)^{b-a-1}$$

to recast the average cap length (23) as

$$\langle k \rangle = -1 + \lambda \left(\frac{e}{\lambda} \right)^\lambda \gamma(\lambda, \lambda), \quad (24)$$

where $\gamma(a, x) = \int_0^x dt t^{a-1} e^{-t}$ is the (lower) incomplete gamma function.

In the realistic limit of $\lambda \gg 1$, we use the large λ asymptotics

$$\gamma(\lambda, \lambda) \rightarrow \frac{1}{2} \Gamma(\lambda), \quad \Gamma(\lambda) \sim \sqrt{\frac{2\pi}{\lambda}} \left(\frac{\lambda}{e} \right)^\lambda,$$

to give

$$\langle k \rangle \rightarrow \sqrt{\pi\lambda/2} \quad \text{as } \lambda \rightarrow \infty. \quad (25)$$

Thus, even though the number of GTP⁺ monomers is equal to λ , only $\sqrt{\lambda}$ of them comprise the microtubule cap, as qualitatively illustrated in Fig. 2. Note that the average cap length is proportional to the square root of the velocity; essentially the same result was obtained from the coarse-grained theory of Flyvbjerg *et al.* [18].

D. Island size distributions

At a finer level of resolution, we determine the distribution of island sizes at the tip of a microtubule (Fig. 3). A simple characteristic of this population is the average number I of GTP⁺ islands. If all GTP⁺ islands were approximately as long as the cap, we would have $I \sim \langle N \rangle / \langle k \rangle \sim \sqrt{\lambda}$. As we shall see, however, I scales linearly with λ because most islands are short. A similar dichotomy arises for negative islands.

To write the master equation for the average number of islands, note that the conversion GTP⁺ \rightarrow GDP⁻ eliminates islands of size 1. Additionally, an island of size $k \geq 3$ splits into two daughter islands, and hence the number of islands increases by one, if conversion occurs at any one of the $k-2$ in the interior of an island as illustrated below:

Conversely, if the cap has length 0, attachment creates a new cap of length 1 at rate λ . The net result of these processes is encoded in the rate equation

$$\frac{dI}{dt} = \sum_{k \geq 1} (k-2)I_k + \lambda n_0, \quad (26)$$

with I_k the average number of GTP⁺ islands of size k .

We now use the sum rules $I = \sum_{k \geq 1} I_k$ and $\langle N \rangle = \sum_{k \geq 1} k I_k$ to recast (26) as

$$\frac{dI}{dt} = \langle N \rangle - 2I + \lambda n_0 \quad (27)$$

from which the steady-state average number of islands is

$$I = \frac{\langle N \rangle + \lambda n_0}{2} = \frac{\lambda}{2} \frac{2 + \lambda}{1 + \lambda}. \quad (28)$$

For large λ , the number of islands approaches $\lambda/2$, while the number of GTP⁺ monomers equals λ . Thus the typical island size is 2. Nevertheless, as we now show, the GTP⁺ and GDP⁻ island distributions actually have power-law tails, with different exponents for each species.

The GTP⁺ island size distribution evolves according to the master equation

$$\dot{I}_k = -kI_k + 2 \sum_{s \geq k+1} I_s + \lambda(n_{k-1} - n_k). \quad (29)$$

This equation is similar in spirit to Eq. (16) for the cap length distribution. As a useful self-consistency check, the sum of Eq. (29) gives (27), while multiplying (29) by k and summing over all $k \geq 1$ gives Eq. (1).

The stationary distribution satisfies

$$kI_k = 2 \sum_{s \geq k+1} I_s + \lambda(n_{k-1} - n_k). \quad (30)$$

Using $\sum_{s \geq 2} I_s = I - I_1$, we transform (30) at $k=1$ to

$$3I_1 = 2I + \lambda(n_0 - n_1).$$

Similarly, using $\sum_{s \geq 3} I_s = I - I_1 - I_2$ we transform (30) at $k=2$ to

$$4I_2 = 2(I - I_1) + \lambda(n_1 - n_2).$$

Thus using (20) and (30) we obtain

$$I_1 = \frac{\lambda}{3} + \frac{4\lambda}{3(1+\lambda)(2+\lambda)}, \quad (31a)$$

$$I_2 = \frac{\lambda}{12} + \frac{25\lambda^2 - 6\lambda}{12(1+\lambda)(2+\lambda)(3+\lambda)}. \quad (31b)$$

The same procedure gives I_k for larger k .

Since the I_k represent the *average* number of islands of size k , they become meaningful only for $\lambda \rightarrow \infty$ where an appreciable number of such islands exist. In this limit, we write I_k more compactly by first rearranging (30) into the equivalent form

$$(k-1)I_{k-1} - (k+2)I_k = \lambda(n_{k-2} - 2n_{k-1} + n_k). \quad (32)$$

We then use (20) and the asymptotic properties of the gamma function to find that the right-hand side of Eq. (32) is

$$\lambda(n_{k-2} - 2n_{k-1} + n_k) = -\frac{3k+1}{\lambda} + O\left(\frac{1}{\lambda^2}\right),$$

and is therefore negligible in the large- λ limit. Thus Eq. (32) reduces to $(k-1)I_{k-1} = (k+2)I_k$, with solution $I_k = A/[k(k+1)(k+2)]$. We find the amplitude A by matching with the exact result, Eq. (31a), to give $I_1 = \lambda/3$ for large λ . The final result is

$$I_k = \frac{2\lambda}{k(k+1)(k+2)}. \quad (33)$$

In the large λ limit, $I = \lambda/2$, and the above result can be rewritten as

$$\frac{I_k}{I} = \frac{4}{k(k+1)(k+2)}. \quad (34)$$

Remarkably, the size distribution of the positive islands is *identical* to the degree distribution of a growing network with strictly linear preferential attachment [25–27].

The results for the island size distribution in the large λ limit are compared to simulation results in Fig. 5. These asymptotic results are expected to apply to island sizes k much smaller than the size of the cap which scales as $\sqrt{\lambda}$. The distributions obtained from the numerical simulations should then obey the theoretical form but with a finite-size cutoff. The results in Fig. 5 are consistent with this picture but, interestingly, the numerical distribution rises above the theoretical curve before falling sharply below it. This anomaly occurs in many heterogeneous growing network models, and it can be fully characterized in terms of finite-size effects [28].

E. Continuum limit, $\lambda \rightarrow \infty$

When $\lambda \rightarrow \infty$, both the length of the cap and the length of the region that contains GTP⁺ become large. In this limit, the results from the discrete master equation can be expressed much more elegantly and completely by a continuum approach. The fundamental feature is that the conversion pro-

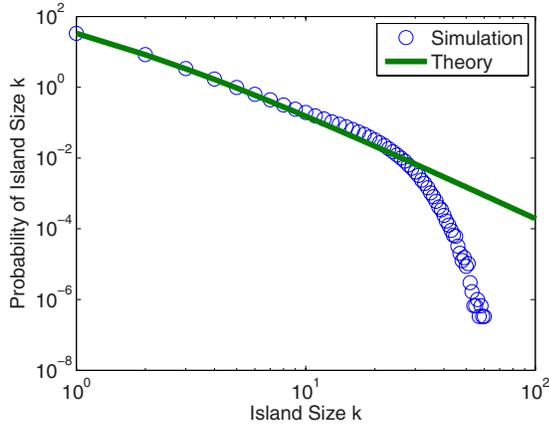

FIG. 5. (Color online) Simulation results at $\mu=0$, $\lambda=100$, and $p=1$ for the size distribution of positive islands, I_k/λ . The solid line is the theoretical prediction of Eq. (33).

cess $\text{GTP}^+ \rightarrow \text{GDP}^-$ occurs independently for each monomer. Since the residence time of each monomer increases linearly with distance from the tip, the probability that a GTP^+ does not convert decays exponentially with distance from the tip. This fact alone is sufficient to derive all the island distributions.

Consider first the length ℓ of the populated region (Fig. 3). For a GTP^+ that is a distance x from the tip, its residence time is $\tau=x/\lambda$ in the limit of large λ . Thus the probability that this GTP^+ does not convert is $e^{-\tau}=e^{-x/\lambda}$. We thus estimate ℓ from the extremal criterion [29]

$$1 = \sum_{x \geq \ell} e^{-x/\lambda} = (1 - e^{-1/\lambda})^{-1} e^{-\ell/\lambda} \quad (35)$$

that merely states that there is of the order of a single GTP^+ further than a distance ℓ from the tip. Since $(1 - e^{-1/\lambda})^{-1} \rightarrow \lambda$ when λ is large, the length of the active region scales as

$$\ell = \lambda \ln \lambda. \quad (36)$$

The probability that the cap has length k is given by

$$(1 - e^{-(k+1)/\lambda}) \prod_{j=1}^k e^{-j/\lambda}.$$

The product ensures that all monomers between the tip and a distance k from the tip are GTP^+ , while the prefactor gives the probability that a monomer is a distance $k+1$ from the tip is a GDP^- . Expanding the prefactor for large λ and rewriting the product as the sum in the exponent, we obtain

$$n_k \sim \frac{k+1}{\lambda} e^{-k(k+1)/2\lambda}, \quad (37)$$

a result that also can be obtained by taking the large- λ limit of the exact result for n_k given in Eq. (20).

Similarly, the probability to find a positive island of length k that occupies sites $x+1, x+2, \dots, x+k$ is

$$(1 - e^{-x/\lambda})(1 - e^{-(x+k+1)/\lambda}) \prod_{j=1}^k e^{-(x+j)/\lambda}. \quad (38)$$

The two prefactors ensure that sites x and $x+k+1$ consist of GDP^- , while the product ensures that all sites between $x+1$ and $x+k$ are GTP^+ .

Most islands are far from the tip and they are relatively short, $k \ll x$, so that (38) simplifies to

$$(1 - e^{-x/\lambda})^2 e^{-kx/\lambda} e^{-k^2/2\lambda}. \quad (39)$$

The total number of islands of length k is obtained by summing the island density (39) over all x . Since $\lambda \gg 1$, we replace the summation by integration and obtain

$$I_k = \int_0^\infty dx (1 - e^{-x/\lambda})^2 e^{-kx/\lambda} e^{-k^2/2\lambda} = \frac{2\lambda}{k(k+1)(k+2)} e^{-k^2/2\lambda}. \quad (40)$$

The power-law tail agrees with Eq. (33), whose derivation explicitly invoked the $\lambda \rightarrow \infty$ limit.

We can also obtain the density of negative islands in this continuum description, a result that seems impossible to derive by a microscopic master equation description. In parallel with (39), the density of negative islands of length $k \ll x$ with one end at x is given by

$$e^{-2x/\lambda} (1 - e^{-x/\lambda})^k, \quad (41)$$

and the total number of negative islands of length k is

$$J_k = \int_0^\infty dx e^{-2x/\lambda} (1 - e^{-x/\lambda})^k = \frac{\lambda}{(k+1)(k+2)}. \quad (42)$$

Again, we find a power-law tail for the GDP^- island size distribution, but with exponent 2. The total number of GDP^- monomers within the populated zone is then $\sum_{k \geq 1} k J_k$. While this sum formally diverges, we use the upper size cutoff, $k_* \sim \lambda$ to obtain $\sum_{k \geq 1} k J_k \approx \lambda \ln \lambda$. Since the length of the populated zone $\ell \sim \lambda \ln \lambda$, this zone therefore predominantly consists of GDP^- islands.

In analogy with the cap, consider now the “tail”—the last island of GDP^- within the populated zone (see Fig. 3). The probability m_k that it has length k is

$$m_k = e^{-\ell/\lambda} (1 - e^{-\ell/\lambda})^k. \quad (43)$$

Using (36) we simplify the above expression to

$$m_k = \lambda^{-1} (1 - \lambda^{-1})^k = \lambda^{-1} e^{-k/\lambda}.$$

Hence, the average length of the tail is

$$\langle k \rangle = \sum_{k \geq 1} k m_k = \lambda, \quad (44)$$

which is much longer (on average) than the cap.

III. CONSTRAINED GROWTH

When $p \neq 1$, the rate of attachment depends on the state of the tip of the microtubule—attachment to a GTP^+ occurs with rate λ while attachment to a GDP^- occurs with rate $p\lambda$.

While this state dependence makes the master equation description for the properties of the tubule more complicated, qualitative features about the structure of the populated zone are the same as those in the case $p=1$. In this section, we outline some of the basic features of the populated zone when $p \neq 1$, but we still keep $\mu=0$.

A. Distribution of GTP⁺

The average number of GTP⁺ monomers now evolves according to the rate equation

$$\frac{d}{dt}\langle N \rangle = -\langle N \rangle + p\lambda n_0 + \lambda(1 - n_0), \quad (45)$$

which should be compared to the rate equation (1) for the case $p=1$. The loss term on the right-hand side describes the conversion GTP⁺ \rightarrow GDP⁻, while the remaining terms represent gain due to attachment to a GTP⁺ with rate λ and to a GDP⁻ with rate $p\lambda$. Here n_0 is the probability for a cap of length zero, that is, the last site is a GDP⁻. The stationary solution to (45) is

$$\langle N \rangle = p\lambda n_0 + \lambda(1 - n_0), \quad (46)$$

so we need to determine n_0 . By extending Eq. (16) to the case $p \neq 1$, we then find that n_0 is governed by the rate equation

$$\dot{n}_0 = -p\lambda n_0 + (1 - n_0). \quad (47)$$

Thus, asymptotically $n_0 = \frac{1}{1+p\lambda}$ and substituting into (46), the average number of GTP⁺ monomers is

$$\langle N \rangle = p\lambda \frac{1 + \lambda}{1 + p\lambda}. \quad (48)$$

More generally, we can determine the distribution of the number of GTP⁺ monomers; the details of this calculation are presented in Appendix B.

B. Growth rate and diffusion coefficient

The growth rate of a microtubule equals $p\lambda$ when the cap length is zero and to λ otherwise. Therefore,

$$V(p, \lambda) = p\lambda n_0 + \lambda(1 - n_0) = p\lambda \frac{1 + \lambda}{1 + p\lambda}. \quad (49)$$

For the diffusion coefficient of the tip of a microtubule, we need its mean-square position. As in the case $p=1$, it is convenient to determine the probability distribution for the tip position. Thus, we introduce $X(L, t)$ and $Y(L, t)$, the probabilities that the microtubule length equals L and the last monomer is a GTP⁺ or a GDP⁻, respectively. These probabilities satisfy

$$\frac{dX(L)}{dt} = \lambda X(L-1) + p\lambda Y(L-1) - (1 + \lambda)X(L), \quad (50a)$$

$$\frac{dY(L)}{dt} = X(L) - p\lambda Y(L). \quad (50b)$$

Summing these equations, the length distribution $P(L) = X(L) + Y(L)$ satisfies

$$\frac{dP(L)}{dt} = \lambda X(L-1) + p\lambda Y(L-1) - \lambda X(L) - p\lambda Y(L). \quad (51)$$

The state of the last monomer does not depend on the microtubule length L for large L . Thus asymptotically

$$X(L) = (1 - n_0)P(L), \quad Y(L) = n_0P(L). \quad (52)$$

Substituting (52) into (51) we obtain a master equation for the tubule length distribution of the same form as Eq. (9), but with prefactor V given by (49) instead of λ . As a result of this correspondence, we infer that the diffusion coefficient is one-half of the growth rate,

$$D(p, \lambda) = \frac{1}{2}p\lambda \frac{1 + \lambda}{1 + p\lambda}. \quad (53)$$

For large λ both the growth rate of the tip of the microtubule and its diffusion coefficient approach the corresponding expressions in Eq. (12) for the case $p=1$.

C. Cap length distribution

The master equations for the cap length distribution are the same as in the $p=1$ case when $k \geq 2$. The master equations for $k=0$ and $k=1$ are slightly changed to account for the different rates at which attachment occurs at a GDP⁻ monomer,

$$p\lambda n_0 = N_1 = 1 - n_0,$$

$$(1 + \lambda)n_1 - p\lambda n_0 = N_2 = 1 - n_0 - n_1.$$

Solving iteratively we recover $n_0 = \frac{1}{1+p\lambda}$ and also obtain

$$n_1 = \frac{2p\lambda}{(1 + p\lambda)(2 + \lambda)}, \quad (54a)$$

$$n_2 = \frac{3p\lambda^2}{(1 + p\lambda)(2 + \lambda)(3 + \lambda)}, \quad (54b)$$

etc. The general solution for the n_k is found by the same method as in Sec. II C to be

$$n_k = (k + 1)\lambda^k \frac{p}{1 + p\lambda} \frac{\Gamma(2 + \lambda)}{\Gamma(k + 2 + \lambda)}, \quad (55)$$

which are valid for $k \geq 1$. With this length distribution, the average cap length is then

$$\langle k \rangle = \frac{p}{1 + p\lambda} \sum_{k \geq 1} k(k + 1)\lambda^k \frac{\Gamma(2 + \lambda)}{\Gamma(k + 2 + \lambda)}, \quad (56)$$

and the sum can again be expressed in terms of hypergeometric series as in Eq. (23). Rather than following this path, we focus on the most interesting limit of large λ . Then the cap length distribution (55) approaches the previous solution (20) for the case $p=1$ and the mean length reduces to (25), independent of p .

D. Island size distribution

For the distribution of island sizes, the master equation remains the same as in the $p=1$ case when $k \geq 2$. However, when $k=1$, the master equation becomes

$$I_1 = 2 \sum_{s \geq 2} I_s + p\lambda n_0 - \lambda n_1 \quad (57)$$

in the stationary state. Then the average number of islands and the average number of islands of size 1 are found from

$$2I = \langle N \rangle + p\lambda n_0, \quad 3I_1 = 2I + p\lambda n_0 - \lambda n_1.$$

Using $n_0 = \frac{1}{1+p\lambda}$ and Eqs. (48) and (54a) we obtain

$$I = \frac{p\lambda}{2} \frac{2 + \lambda}{1 + p\lambda}, \quad (58a)$$

$$I_1 = \frac{p\lambda}{1 + p\lambda} \left(\frac{\lambda}{3} + \frac{2 + \lambda/3}{2 + \lambda} \right). \quad (58b)$$

Again, in the limit of large λ , the average island size distribution reduces to our previously-quoted results in (33) or equivalently (34). The leading behavior in the $\lambda \rightarrow \infty$ limit is again independent of p .

IV. INSTANTANEOUS DETACHMENT

For $\mu > 0$, a microtubule can recede if its tip consists of GDP⁻. The competition between this recession and growth by the attachment of GTP⁺ leads to a rich dynamics in which the microtubule length can fluctuate wildly under steady conditions. In this section, we focus on the limiting case of infinite detachment rate, $\mu = \infty$. In this limit, any GDP⁻ monomer(s) at the tip of a microtubule are immediately removed. Thus the the tip is always a GTP⁺; this means that the parameter p become immaterial. Finally, for $\mu = \infty$, we also require the growth rate $\lambda \rightarrow \infty$ to have a microtubule with an appreciable length. This is the limit considered below.

As soon as the last monomer of the tubule changes from a GTP⁺ to a GDP⁻, a string of k contiguous GDP⁻ monomers exist at the tip and they detach immediately. We term such an event an *avalanche of size k*. We now investigate the statistical properties of these avalanches.

A. Catastrophes

The switches from a growing to a shrinking state of a microtubule are called *catastrophes* [8]. If in a newly attached GTP⁺ at the tip converts to a GDP⁻ and the rest of the microtubule consists only of GDP⁻ at that moment, the microtubule instantaneously shrinks to zero length, a phenomenon that can be termed a *global catastrophe*. We now de-

termine the probability for such a catastrophe to occur. Formally, the probability of a global catastrophe is

$$\mathcal{C}(\lambda) = \frac{1}{1 + \lambda} \prod_{n=1}^{\infty} (1 - e^{-n/\lambda}). \quad (59)$$

The factor $(1 + \lambda)^{-1}$ gives the probability that the monomer at the tip converts to a GDP⁻ before the next attachment event, while the product gives the probability that the rest of the microtubule consists of GDP⁻. In principle, the upper limit in the product is set by the microtubule length. However, for $n > \lambda$, each factor in the product is close to 1 and the error made in extending the product to infinity is small. The expression within the product is obtained under the assumption that the tubule grows steadily between these complete catastrophes and the smaller, local catastrophes, are therefore ignored in this calculation.

The leading asymptotic behavior of the infinite product in (59) is found by expressing it in terms of the Dedekind η function [30]

$$\eta(z) = e^{i\pi z/12} \prod_{n=1}^{\infty} (1 - e^{2\pi i n z}), \quad (60)$$

and using a remarkable identity satisfied by this function,

$$\eta(-1/z) = \sqrt{-iz} \eta(z).$$

For our purposes, we define $a = -i\pi z$ to rewrite this identity as

$$\prod_{n=1}^{\infty} (1 - e^{-2an}) = \sqrt{\frac{\pi}{a}} e^{(a-b)/12} \prod_{n=1}^{\infty} (1 - e^{-2bn}),$$

where $b = \pi^2/a$. Specializing to the case $a = (2\lambda)^{-1}$ yields

$$\mathcal{C}(\lambda) = \frac{\sqrt{2\pi\lambda}}{1 + \lambda} e^{-\pi^2\lambda/6} e^{1/24\lambda} \prod_{n \geq 1} (1 - e^{-4\pi^2\lambda n}) \sim \sqrt{\frac{2\pi}{\lambda}} e^{-\pi^2\lambda/6}. \quad (61)$$

Since the time between catastrophes scales as the inverse of the occurrence probability, this interevent time becomes very long for large λ .

B. Avalanche size distribution

In the instantaneous detachment limit, $\mu = \infty$, the catastrophes are avalanches whose size is determined by the number of GDP⁻ between the tip and the first GTP⁺ island. A global catastrophe is an avalanche of size equal to the length of the tubule, whose occurrence probability was calculated in the preceding section. Similar arguments can be used to calculate the size distribution of the smaller avalanches.

Since the cap is large when λ is large, an avalanche of size 1 arises only through the reaction scheme

where the first step occurs at rate 1 and the second step is instantaneous. Since attachment proceeds with rate λ , the probability that conversion occurs before attachment is

$A_1=(1+\lambda)^{-1}$; this expression gives the relative frequency of avalanches of sizes ≥ 1 . Analogously, an avalanche of size 2 is formed by the events

$$|\cdots + + + \rangle \Rightarrow |\cdots + - + \rangle \Rightarrow |\cdots + - - \rangle \Rightarrow |\cdots + \rangle,$$

and the probability that the first two steps occur before an attachment event is $A_2 \sim \lambda^{-2}$ to lowest order. At this level of approximation, the relative frequency of avalanches of size equal to 1 is $A_1 - A_2 \sim \lambda^{-1}$. Since we are interested in the regime $\lambda \gg 1$, we shall only consider the leading term in the avalanche size distribution.

Generally an avalanche of size k is formed if the system starts in the configuration

$$|+ \underbrace{+ \cdots +}_{k-1} + \rangle,$$

then $k-1$ contiguous GTP^+ monomers next to the tip convert, and finally the GTP^+ at the tip converts to GDP^- before the next attachment event. The probability for the first $k-1$ conversion events is $\lambda^{-(k-1)}(k-1)!$, where the factorial arises because the order of these steps is irrelevant. The probability of the last step is λ^{-1} . Thus, the relative frequency of avalanches of size k is

$$A_k \sim \lambda^{-k} \Gamma(k). \quad (62)$$

The result can also be derived by the approach of Sec. II E. We use the fact that the configuration

$$|+ \underbrace{- \cdots -}_{k-1} + \rangle$$

occurs with probability $\prod_{1 \leq n \leq k-1} (1 - e^{-n/\lambda})$. Multiplying by the probability that the monomer at the tip converts before the next attachment event then gives the probability for an avalanche of size k ,

$$A_k = (1 + \lambda)^{-1} \prod_{n=1}^{k-1} (1 - e^{-n/\lambda}). \quad (63)$$

Using $1 - e^{-n/\lambda} = n/\lambda$ we recover (62). If we expand the exponent to the next order, $1 - e^{-n/\lambda} \approx n/\lambda - n^2/(2\lambda^2)$, Eq. (63) becomes

$$A_k = \lambda^{-k} \Gamma(k) \prod_{n=1}^{k-1} \left(1 - \frac{n}{2\lambda}\right) \sim \lambda^{-k} \Gamma(k) e^{-k^2/4\lambda}.$$

V. GENERAL GROWTH CONDITIONS

The general situation where the attachment and detachment rates, λ and μ , have arbitrary values, and where the parameter $p \neq 1$ seems analytically intractable because the master equations for basic observables are coupled to an infinite hierarchy of equations to higher-order variables. For example, the quantity $n_0 \equiv \text{Prob}\{-\}$, the probability for a cap of length zero, satisfies the exact equation

$$\dot{n}_0 = -p\lambda n_0 + (1 - n_0) - \mu \mathcal{N}_0, \quad (64)$$

and the speed of the tip is

$$V(\lambda, \nu, p) = p\lambda n_0 + \lambda(1 - n_0) - \mu n_0. \quad (65)$$

Here $\mathcal{N}_0 \equiv \text{Prob}\{+-\}$ is the probability that there is a GDP^- at the front position with a GTP^+ on its left. Thus, to determine n_0 we must find \mathcal{N}_0 , which then requires higher-order correlation functions, etc. This hierarchical nature prevents an exact analysis and we turn to approximate approaches to map out the behavior in different regions of the parameter space.

A. Limiting cases

For $\lambda, \mu \ll 1$, the conversion $\text{GTP}^+ \rightarrow \text{GDP}^-$ at rate one greatly exceeds the rates $\lambda, p\lambda, \mu$ of the other three basic processes that govern microtubule dynamics. Hence, we can assume that conversion is instantaneous. Consequently, the end of a microtubule consists of a string of GDP^- , $|\cdots - - - \rangle$, in which the tip advances at rate $p\lambda$ and retreats at rate μ . Thus from (65) the speed of the tip is

$$V(p, \lambda, \mu) = p\lambda - \mu \quad (66)$$

when $p\lambda > \mu$.

On the other hand, for $\lambda \gg 1$, $n_0 \equiv \text{Prob}\{-\}$ is small and $\text{Prob}\{- - -\}$ is exceedingly small. Hence $n_0 = \text{Prob}\{- - -\} + \mathcal{N}_0 \approx \mathcal{N}_0$. Substituting this result into (64) and solving for n_0 we find

$$n_0 = \frac{1}{1 + p\lambda + \mu}. \quad (67)$$

Note that indeed $n_0 \ll 1$ when $\lambda \gg 1$. Using (67) in (65) we obtain the general result for the growth velocity

$$V = \lambda - \frac{(1-p)\lambda + \mu}{1 + p\lambda + \mu} \quad \text{when } \lambda \gg 1. \quad (68)$$

B. The phase boundary

A basic characteristic of microtubule dynamics is the phase boundary in the parameter space that separates the region where the microtubule grows without bound and a region where the mean microtubule length remains finite. For small λ , this boundary is found from setting $V=0$ in Eq. (66) to give $\mu_* = p\lambda$ for $\lambda \ll 1$. The phase boundary is a straight line in this limit, but for larger λ the boundary is a convex function of λ (see Fig. 6). We can compute the velocity to second order in μ and λ by assuming $\mathcal{N}_0=0$ and then using (64) and (65). This leads to the phase boundary

$$\mu_* = p\lambda + p\lambda^2, \quad (69)$$

that is both convex and more precise. On this phase boundary, the average tubule length grows as \sqrt{t} .

When λ is large, Eq. (68) implies that V is positive and it reduces to $V = \lambda - 1$ for $\mu \gg \lambda$. This simple result follows from the fact that recession of the microtubule is controlled by the unit conversion rate. As soon as conversion occurs, detachment occurs immediately for $\mu \gg \lambda$ and the microtubule recedes by one step. Since advancement occurs at rate

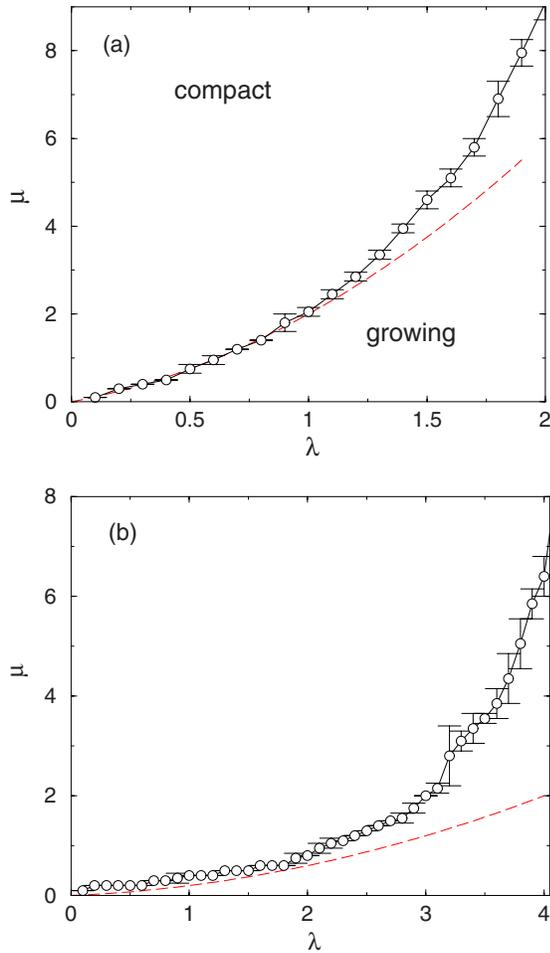

FIG. 6. (Color online) Phase diagrams of a microtubule from simulations for (a) $p=1$ and (b) $p=0.1$. The dashed line represents the prediction (69) that is appropriate for small μ . The extremes of the error bars are the points for which the tubule velocities are 0.005 and 0.015, and their average defines the data point.

λ , the speed of the tip is simply $\lambda-1$. However, for extremely large μ the prediction $V=\lambda-1$ breaks down and the microtubule becomes compact. To determine the phase boundary in this limit, consider first the case $\mu=\infty$. As shown in the preceding section, the probability of a catastrophe roughly scales as $e^{-\pi^2\lambda/6}$ so that the typical time between catastrophes is $e^{\pi^2\lambda/6}$. Since $V=\lambda-1$, the typical length of a microtubule just before a catastrophe is $(\lambda-1)e^{\pi^2\lambda/6}$. Suppose now the detachment rate μ is very large but finite. The microtubule is compact if the time to shrink a microtubule of length $\lambda e^{\pi^2\lambda/6}/\mu$ is smaller than the time $(p\lambda)^{-1}$ required to generate a GTP⁺ by the attachment $|\cdots\rangle \Rightarrow |\cdots+\rangle$ and thereby stop the shrinking. We estimate the location of the phase boundary by equating the two times to give

$$\mu_* \sim p\lambda^2 e^{\pi^2\lambda/6} \quad \text{when } \lambda \gg 1. \quad (70)$$

We checked the theoretical predictions (69) and (70) for the phase boundary numerically (Fig. 6). For small λ , the agree-

ment between theory and the simulation is excellent. For larger λ , the tubule growth is more intermittent and it becomes increasingly difficult to determine the phase boundary with precision. Nevertheless, the qualitative expectations of our theory remain valid.

C. Fluctuations of the tip

Finally, we study the fluctuations of the tip in the small and large λ limits. In the former case but also on the growth phase $p\lambda > \mu$, the tip undergoes a biased random walk with diffusion coefficient

$$D(p, \lambda, \mu) = \frac{p\lambda + \mu}{2} \quad \text{when } 1 \gg p\lambda > \mu. \quad (71)$$

For large λ , the analysis is simplified by the principle that can be summarized by the following sentence: ‘‘The leading behaviors in the $\lambda \rightarrow \infty$ limit are universal, that is, independent of p and μ .’’ This is not true if p is particularly small (like λ^{-1}) and/or if μ is particularly large [like μ_* given by (70)]. But when $p\lambda \gg 1$ and $\mu \ll \mu_*$, the above principle is true, and

$$V = \lambda, \quad D = \frac{\lambda}{2} \quad (72)$$

in the leading order.

The computation of subleading behaviors is more challenging. We merely state here two asymptotic results. When $\mu \ll \lambda$, we again have the relation $D=V/2$, with $V=\lambda+1-p^{-1}$. If $\mu_* \gg \mu \gg \lambda \gg 1$, we find

$$V = \lambda - 1, \quad D = \frac{\lambda + 1}{2}. \quad (73)$$

The derivation of the latter uses the probabilities $X(L, t)$ and $Y(L, t)$ and follows similar steps as in Sec. III B.

VI. SUMMARY

We investigated a simple dynamical model of a microtubule that grows by attachment of a GTP⁺ to its end at rate λ , irreversible conversion of any GTP⁺ to GDP⁻ at rate 1, and detachment of a GDP⁻ from the end of a microtubule at rate μ . Remarkably, these simple update rules for a one-dimensional system lead to steady growth, wild fluctuations, or a steady state. Our model has a minimalist formulation and therefore is not meant to account for all of the microscopic details of microtubule dynamics. Rather, our main goal has been to solve for the structural and dynamical properties of this idealized microtubule model. Some of the quantities that we determined, such as island size distributions, have not been studied previously. Thus our predictions about the cap and island size distributions may help motivate experimental studies of these features of microtubules.

A rich phenomenology was found as a function of the three fundamental rates in our model. When GTP⁺ attachment is dominant ($\lambda \gg 1$) and the attachment is independent

of the identity of the last monomer on the free end of the microtubule ($p=1$), the GTP⁺ and GDP⁻ organize into alternating domains, with gradually longer GTP⁺ domains and gradually shorter GDP⁻ domains toward the tip of the microtubule (Fig. 2). Here, the parameter λ could naturally be varied experimentally by either changing the temperature or the concentration of tubulins (free GTP⁺) in the solution.

The basic geometrical features in this growing phase of a microtubule can be summarized as follows:

Symbol	Meaning	Scaling behavior
N	No. of GTP ⁺ monomers	λ
L	Tubule length	λt
$\langle k \rangle$	Average cap length	$\sqrt{\pi\lambda/2}$
I	No. of islands	$\lambda/2$
I_k	No. of GTP ⁺ k islands	$2\lambda/k^3$
J_k	No. of GDP ⁻ k islands	λ/k^2

We emphasize that the island size distributions of GTP⁺ and GDP⁻ are robust power laws with respective exponents of 3 and 2. In the limit of $p \ll 1$, in which attachment is suppressed when a GDP⁻ is at the free end of the microtubule, the average number of GTP⁺ monomers on the microtubule asymptotically is $p\lambda$, while the rest of the results in the above table remain robust in the long-time limit.

Conversely, when detachment of GDP⁻ from the end of the tubule is dominant (detachment rate $\mu \rightarrow \infty$, a rate that also could be controlled by the temperature), the microtubule length remains bounded but its length can fluctuate strongly. When the attachment rate is also large, the strong competition between attachment and detachment leads to wild fluctuations in the microtubule length even with steady external conditions. We developed a probabilistic approach that shows that the time between catastrophes, where the microtubule shrinks to zero length, scales exponentially with the attachment rate λ . Thus, a microtubule can grow essentially freely for a very long time before undergoing a catastrophe.

For the more biologically relevant case of intermediate parameter values, we extended our theoretical approaches to determine basic properties of the tubule, such as its rate of growth, fluctuations of the tip around this mean growth behavior, and the phase diagram in the (λ, μ) parameter space. In this intermediate regime, numerical simulations provide a more detailed picture of the geometrical structure and time history of a microtubule.

APPENDIX A: JOINT DISTRIBUTION FOR $p=1$

Introducing the two-variable generating function

$$\mathcal{P}(x, y, t) = \sum_{L \geq N \geq 0} x^L y^N P(L, N, t), \quad (\text{A1})$$

we recast (13) into a partial differential equation

$$\frac{\partial \mathcal{P}}{\partial t} = (1-y) \frac{\partial \mathcal{P}}{\partial y} - \lambda(1-xy)\mathcal{P}. \quad (\text{A2})$$

Writing

$$\mathcal{P}(x, y, t) = e^{\lambda[xy - (1-x)\ln(1-y)]} \mathcal{Q}(x, y, t), \quad (\text{A3})$$

we transform (A2) into a wave equation for an auxiliary function $\mathcal{Q}(x, y, t)$,

$$\frac{\partial \mathcal{Q}}{\partial t} = (1-y) \frac{\partial \mathcal{Q}}{\partial y}, \quad (\text{A4})$$

whose general solution is

$$\mathcal{Q}(x, y, t) = \Phi[x, \ln(1-y) - t]. \quad (\text{A5})$$

The initial condition $P(L, N, 0) = \delta_{L,0} \delta_{N,0}$ implies $\mathcal{P}(x, y, 0) = 1$ and, therefore,

$$e^{\lambda[xy - (1-x)\ln(1-y)]} \Phi[x, \ln(1-y)] = 1,$$

from which

$$\Phi(a, b) = e^{\lambda[(1-a)b + a(e^b - 1)]}. \quad (\text{A6})$$

Combining Eqs. (A3), (A5), and (A6) we arrive at

$$\lambda^{-1} \ln \mathcal{P} = xy(1 - e^{-t}) - t - x(1 - e^{-t} - t). \quad (\text{A7})$$

APPENDIX B: JOINT DISTRIBUTION FOR $p \neq 1$

For $p \neq 1$, we consider the distributions X_N and Y_N , defined as the probabilities to have N GTP⁺ monomers with the tip being either GTP⁺ or GDP⁻, respectively. These probabilities satisfy a closed set of coupled equations. In the stationary state these equations become

$$(N + \lambda)X_N = \lambda X_{N-1} + p\lambda Y_{N-1} + NX_{N+1}, \quad (\text{B1a})$$

$$(N + p\lambda)Y_N = X_{N+1} + (N + 1)Y_{N+1}. \quad (\text{B1b})$$

Since $X_0 \equiv 0$, it is convenient to define the generating functions corresponding to X_N and Y_N as follows:

$$\mathcal{X}(z) = \sum_{N \geq 1} z^{N-1} X_N, \quad (\text{B2a})$$

$$\mathcal{Y}(z) = \sum_{N \geq 0} z^N Y_N. \quad (\text{B2b})$$

Now multiply Eq. (B1a) by z^N and Eq. (B1b) by z^{N-1} and sum over all $N \geq 1$ or $N \geq 0$, respectively, to obtain

$$p\lambda \mathcal{Y} = \mathcal{X} - \zeta(\mathcal{X} - \mathcal{X}'), \quad (\text{B3a})$$

$$p\lambda\mathcal{Y} = \mathcal{X} - \zeta\mathcal{Y}', \quad (\text{B3b})$$

where $\zeta = \lambda(z-1)$ and the prime denotes a derivative in ζ . We can reduce these two coupled first-order differential equations to uncoupled second-order equations

$$\zeta\mathcal{X}'' + (2 + p\lambda - \zeta)\mathcal{X}' - (1 + p\lambda)\mathcal{X} = 0, \quad (\text{B4a})$$

$$\zeta\mathcal{Y}'' + (2 + p\lambda - \zeta)\mathcal{Y}' - p\lambda\mathcal{Y} = 0. \quad (\text{B4b})$$

The solutions are the confluent hypergeometric functions

$$\mathcal{X}(z) = \frac{p\lambda}{1 + p\lambda} F(1 + p\lambda; 2 + p\lambda; \zeta), \quad (\text{B5a})$$

$$\mathcal{Y}(z) = \frac{1}{1 + p\lambda} F(p\lambda; 2 + p\lambda; \zeta). \quad (\text{B5b})$$

These generating functions have seemingly compact expressions but one must keep in mind that the X and Y probabilities are actually infinite sums. For instance, $Y_0 = \mathcal{Y}(z=0) = \mathcal{Y}(\zeta = -\lambda)$. Recalling the definition of the confluent hypergeometric function we obtain

$$Y_0 = \frac{1}{1 + p\lambda} F(p\lambda; 2 + p\lambda; -\lambda) = \frac{1}{1 + p\lambda} \sum_{n \geq 0} \frac{(p\lambda)_n}{(2 + p\lambda)_n} \frac{(-\lambda)^n}{n!},$$

where $(a)_n = a(a+1)\cdots(a+n-1) = \Gamma(a+n)/\Gamma(a)$ is the rising factorial. Note that $\Pi_0 = Y_0$. Computing

$$X_1 = \frac{p\lambda}{1 + p\lambda} F(1 + p\lambda; 2 + p\lambda; -\lambda),$$

$$Y_1 = \lambda \frac{p\lambda}{(1 + p\lambda)(2 + p\lambda)} F(1 + p\lambda; 3 + p\lambda; -\lambda),$$

one can determine $\Pi_1 = X_1 + Y_1$. Some of these formulas can be simplified using the Kummer relation

$$F(a; b; \zeta) = e^\zeta F(b - a; b; -\zeta).$$

For instance,

$$Y_0 = \sum_{n \geq 0} \frac{(n+1)\lambda^n e^{-\lambda}}{(1 + p\lambda)_{n+1}},$$

$$X_1 = p\lambda \sum_{n \geq 0} \frac{\lambda^n e^{-\lambda}}{(1 + p\lambda)_{n+1}},$$

$$Y_1 = p\lambda^2 \sum_{n \geq 0} \frac{(n+1)\lambda^n e^{-\lambda}}{(1 + p\lambda)_{n+2}}.$$
